Abstract
One of the known and rare complications of the colon cancer is perforation, with fistulas or abscesses formation. In this paper it is reported the case of a 61 year old man who presented himself with pain and a palpable mass in the right upper abdominal quadrant in association with fever and weight loss. The radiological investigation showed findings compatible with perforated colon cancer and hepatic fistulization. An emergent surgery was performed and confirmed the radiologic suspicion.

Key-words
Colon cancer; Perforation; Hepatic fistulization.

Introduction
The incidence of colon cancer has increased among colorectal cancers1. Many complications can appear in patients with colon cancer which requires emergent surgical management such as acute bowel obstruction, perforation, ischemic colitis and intussusception2. These complications can obscure clinically and/or radiologically the underling colon cancer and they may result in a delayed diagnosis and treatment3. Perforation and penetration of adjacent organs with intra-abdominal abscess4 or fistula formation are rare initial presentations of the colon cancer, being the carcinoma the minor cause of gastrointestinal fistula5.

Case Presentation
A 61-year-old man presented to our department with abdominal pain in the right upper quadrant, for two weeks, in association with fever and weight loss. At physical examination the patient had a palpable tumefaction in the right upper quadrant. Laboratorial investigation revealed anemia, mild hyposubalumemia, elevated white cell blood count and C-reactive protein. The abdominal X-ray showed pocketed air collections, with round shape and irregular borders, in the topography of the right upper quadrant (Fig. 1). An ultrasound scan was performed. It revealed a heterogeneous mass adjacent to the hepatic parenchyma and to colonic loops, at the right upper quadrant (Fig. 2). In order to characterise the lesion an abdominal Computed Tomography (CT) was...
performed. The CT showed a collection with multiloculated and heterogeneous appearance located in the hepatic parenchyma with a sinus tract to the adjacent loop of the ascending colon. It also showed stranding of the pericolic fat and free peritoneal fluid. (Figs. 3, 4, 5).

An emergent surgery was performed and confirmed the presence of a mass involving the hepatic colonic angle, the liver and the abdominal wall. During the surgery fecal material was drained and two drain tubes were placed, one in sub-hepatic position and another one was placed adjacent to the colonic perforation. A loop ileostomy was performed. The histological result of the intraoperative collected material that revealed necrotic tissue and architectural aspects that suggested neoplastic etiology. The patient died a few days after the surgery.

Discussion

Perforation caused by colon cancer is rare in clinical practice, its frequency rounds 2.5-10% of patients with colon cancer. The majority of perforation cases occur in patients with acute obstruction. Only in a few amount of colon cancer cases ulcerations are present, usually due to penetration of the tumour mass through the intestinal wall. Perforation can appear as a free perforation to the peritoneum or as a localized perforation with an abscess or fistula formation. Haldane in 1862 was the first author to describe malignant fistula of the gastrointestinal tract. When the fistulous tract occurs between the colon and adjacent structures, it can result in an abscess formation, as occurs in the case here reported.

Clinical presentation of a perforated colon cancer is characterized by a palpable abdominal mass, abdominal pain, and anemia. There are many potential causes of colonic perforation, including malignant neoplasm, diverticulitis, trauma, ischemia, inflammatory bowel disease and stercoral colitis.
These causes of colonic perforation can be diagnosed by CT. When colonic perforation is present, CT can show a focal defect in the colon wall that may be accompanied by a fluid-density abscess, pneumoperitoneum or stranding of the pericolic fat. There are some specific CT findings that are more commonly found in colon cancer than in benign conditions, such as irregular wall colon thickening, pericolic lymphadenopathy and gas within the tumour. A perforated colon carcinoma has a poor prognosis and a higher surgical mortality, associated with intra-abdominal sepsis and locally advanced malignancy. The best patient management depends on the establishment of the diagnosis of both neoplasia and perforation. When a colon cancer perforation is confirmed, an emergency surgery should be done immediately, in association with systemic support and antibiotic treatment. In the presence of a ruptured and unresectable tumour, a proximal double-lumen colostomy should be performed, during which the lesion should be adequately repaired and washed, along with adequate drainage.

Perforation of a colon cancer with hepatic fistulization is an atypical presentation of colon cancer, which requires a prompt diagnosis and management. CT is the best imaging modality to diagnose this complication. Furthermore we believe that this modality is reliable for facilitating a pre-operative diagnosis in this type of colon cancer complications.
